SUMMARY: Total transection of the retrohepatic inferior vena cava from blunt trauma is a rare and usually fatal injury. Such an injury in a patient with total situs inversus and previous surgical correction of great vessel transposition is described. A possible mechanism for the injury is suggested.

Case Presentation
A 13 year old male was admitted to hospital one hour after being struck on the left side by a van travelling at 20mph. Initial examination showed him to be conscious, orientated and shocked with a blood pressure of 90/60mm Hg and a pulse of 120/minute. The only external injury was a laceration on the left temple. Left abdominal tenderness was present. The boy's mother stated that her son had total situs inversus, had undergone surgical correction for transposition of the great vessels at the age of one year, since when he had been well.

X-rays confirmed the situs inversus, and revealed a left pneumothorax but no bony injuries. Ultrasound demonstrated free fluid in the abdomen and suggested damage to the left lobe of the liver which, of course, was the larger in this case. Resuscitation was begun with colloid and crystalloid and a chest drain was inserted.

He was taken to theatre and a laparotomy was performed. Approximately 1.5 litres of blood was aspirated from the abdomen, and the lateral half of the left lobe of the liver was found to be very extensively lacerated. There was also a small retroperitoneal haematoma. There appeared to be no other injuries and a left hemihepatectomy was begun. During mobilisation of the liver, torrential haemorrhage occurred from the retrohepatic region. The source for this was found to be a completely transected inferior vena cava (IVC) at the level of the diaphragm. Despite packing, massive blood transfusion, control of haemorrhage with balloon catheters, and thoracotomy in an attempt to gain control of the intrapericardial IVC, with subsequent bypass and isolation of the injured segment, control haemorrhage with transfusion of blood through the proximal catheter to increase venous return was unsuccessful. The post mortem findings suggest that the injury to the IVC was caused by shearing forces between the mass of adhesions binding it to the heart and diaphragm and its delicate and relatively immobile infradiaphragmatic portion.

Discussion
Injuries to the IVC have a high mortality rate. Predictors of poor survival are blunt trauma, the presence of shock on admission, retro-hepatic injury and the presence of injury to other organs. This case fulfils all of these criteria. Mortality rates of 75–100% have been quoted for such injuries.

Reports from major trauma centres suggest that the mainstays of treatment are full and adequate resuscitation, recognition of the injury, proximal and distal control of the IVC and, if necessary, thoracotomy to control the intra-pericardial IVC, with subsequent bypass and isolation of the injured segment. Other reports have suggested the use of balloon catheters to control haemorrhage with transfusion of blood through the proximal catheter to increase venous return. Nearly all reports stress the importance of good transfusion facilities and quote replacement blood volumes as high as 30 units. Small district general hospitals do not hold large stores of bank blood and the use of autologous transfusion devices could be of great value in this situation.

The site of this injury (at the level of the diaphragm) made local control impossible. Control via a thoracotomy proved unsuccessful due to the adhesions around the previous operation site. It should be noted that thoracotomy, even for the initial correction of great vessel transposition, is often made difficult by the inaccessibility of the IVC, and does not always allow precise control. It is not surprising therefore that difficulty was experienced in this case.

The post mortem findings suggest that the injury to the IVC was caused by shearing forces between the mass of adhesions binding it to the heart and diaphragm and its delicate and relatively immobile infradiaphragmatic portion.

Conclusion
Early recognition of these injuries, massive transfusion and the availability of adequate bypass facilities are the major means by which the high mortality of retro-hepatic caval injuries can be reduced.
